# 1 Effects of pitch selection randomization on performance

#### 1.1 Motivation

The importance of randomizing pitch selection is fairly obvious, if a pitcher is utterly predictable, the batter is at an enormous advantage. For example, a pitcher that only throws breaking balls outside the strike zone on a 0-2 count would never get an out on that pitch, as every batter would take the pitch. Equally, a pitcher that throws a fastball in the middle of the zone to ensure a strike every time he's on a 3-0 count would get rocked.

The concern of this article is not if pitch selection randomization affects pitcher performance, but how much. A secondary concern is if human randomization can be captured with the standard randomization tests.

To try to answer this we're using three methods. Randomness can be tested in many ways, but two of the main ones are frequency and sequence testing. The first two methods try the frequency approach, while the third does sequence.

The rest of the article is as follows. The basic model for statistical testing is described in section 1.2. In section 1.3 there is a brief description of each randomness test applied and their results. Conclusions and some further avenues of research are presented in section 1.4. Finally, after that, bibliographical references and an appendix with tables with full results from the tests for each player.

#### 1.2 Model

In order to study this question we're using the simplest model possible:

$$Y_n = \alpha + \beta X_n + \epsilon_n \tag{1}$$

Where  $Y_n$  is the FIP- of the player,  $\alpha$  is a constant,  $\beta$  the corresponding coefficient for  $X_n$ , the statistic used in each test, and  $\epsilon_n$  an error term.

Using FIP as the independent variable gives us a picture of the pitcher performance clean of confounding factors like defense, luck and event sequencing. Furthermore, using FIP-, instead of FIP, allows us to control for park and league effects.

Given that FIP- is expressed as a percentage variation, it only makes sense to use a logarithmic transformation of the regressor in each case.

It's important to note that in both sides of the equation a smaller number is better<sup>1</sup>, so, instead of the intuitive result, we're expecting positive values for  $\beta$ .

## 1.3 Testing

Using the dataset provided we constructed two main new variables. First, using pitchType we classified pitches either as fastballs or as off-speed pitches. FA, FT, FF, FC and FS were classified as fastballs. CH, CU, SL, SI, FO, KN, KC, SC, GY and EP were classified as off-speed. All pitches classified as PO, IN, AB, AS and UN were dropped.

Second, using px, pz, szt, szb, we classified each pitch as a strike or a ball.

<sup>&</sup>lt;sup>1</sup>This is not actually true in every case for the right side, but it only comes up once in the dataset.

We limit the study to qualified starting pitchers from both leagues to ensure the pitch sequences are long enough to satisfy the test requirements.

## 1.3.1 $\chi^2$ test

The  $\chi^2$  test is the first stop when testing for randomness. The basic procedure<sup>2</sup> of this test is the comparison between the frequency of realized observations and the expected frequency. It does it by adding the squared difference in the realized observations and their expectation in each category. Let's call the realized observation that fall in category s  $Y_s$ , total number of observations, n, number of categories, k, the expectation of each category  $p_s$ , and the statistic we're constructing, V. V is then constructed according to:

$$V = \sum_{1 \le s \le k} \frac{(Y_s - np_s)^2}{np_s}$$

The statistic V behaves, under some assumptions, like the  $\chi^2$  distribution. Thus we can check against its critical values table to test our hypothesis.

As stated, we will use fastball and off-speed pitches as our categories. In order to avoid using the same data to compute the expectancy and run the test, we obtain the league wide fastball frequencies from the year 2013 and 2014, i.e., 0.55 and 0.54, respectively, with weighted average, 0.54.

After constructing the statistic, we can see that all but five of the pitchers tested fail to approach a random selection. Most notable is Chris Archer, from the Tampa Bay Rays, who is the only one to fail because he's too close to the expected numbers.

As an example of an actionable item derived from this, we can say that David Price, from the Boston Red Sox, has failed in this measure because he's over representing his fastballs and should throw them around 20% less.

When analyzed under the model stated in section 1.2 we see that the relation is statistically significant<sup>3</sup> at the 99% level. A one percent change in this measure is expected to bring down the FIP- of the pitcher almost two points. To continue with the Price example, the implementation of the change, in theory, would bring down his FIP- almost 13 points.

### 1.3.2 Expanded $\chi^2$ test

We can expand our analysis space if we also consider the decision of throwing for a strike. In this fashion we now have four contingent categories, i.e. fastball/strike, fastball/ball, off-speed/strike and off-speed/ball. As in the previous test, the expected frequencies for strikes were computed from the years 2013 and 2014, their weighted average is 0.69.

Under this test every pitcher fails the test. This time, we'll use as an example Madison Bumgarner, from the San Francisco Giants, he mainly fails the test because he over represented the off-speed pitches outside the zone. The test suggest a drop of 31% that goes mainly to fastballs outside the zone.

Unfortunately, this model is not statistically significant at any relevant level. Still, it's may be valuable as showing a model for expansion in this line of research. We'll revisit this later.

<sup>&</sup>lt;sup>2</sup>Knuth (1981)

<sup>&</sup>lt;sup>3</sup>See table 1

#### 1.3.3 Maurer test

Let's, once again, consider only the fastball/off-speed dimension. Aside from frequencies, another way of evaluating randomness is sequences. If we call fastballs 1 and off-speed, 0, the series of pitches thrown during the year can be taken as the product of a random bit generator. As such, we can examine it using the test introduced by Ueli M. Maurer in 1992<sup>4</sup>.

The test functions as the sum of the distance between a block and the last time it appeared in the series. Formally, let the sequence  $s^N$  be divided in non overlapping blocks of length L, K is the number of steps of the test, Q the number of initialization steps and the statistic to be constructed  $fT_U(s^N)$ .  $fT_U(s^N)$  is then constructed according to:

$$fT_{U}\left(s^{N}\right) = \frac{1}{K} \sum_{n=Q+1}^{Q+K} \log_{2} A_{n}\left(s^{N}\right)$$

The distribution of the test and its critical values can be found in the referenced paper, but of special note, as a transformation of a normal distribution, it's symmetrical. Thus, instead of the statistic, we're using the distance from the mean of the distribution as the regressor in the model. The block size selected was 3, given that the sequences are a little shorter than optimal, for example, in average NL qualified pitchers threw 3048 pitches last year.

We can see that all but two pitchers pass the test<sup>5</sup>. On the other hand, Chris Archer sequencing is virtually perfect, followed by Francisco Liriano, Chris Sale and Clayton Kewshaw.

Admittedly, it's harder to find actionable items under this measure.

The model is statistically significant at the 99% level, and percentual changes are almost twice as effective in magnitude as frequency adjustments.

Table	1. Icst an	arysis resur	.05

Table 1: Test analysis results

#### 1.4 Conclusion

We started with two main questions: Can the standard randomness tests work (or, more properly, pass) a human generated random sequence? and how big is the effect of pitch selection randomness in pitcher performance?

Both get satisfactory answers. For the first one, in particular in Maurer Test, almost every pitcher passes the test. As for the second, we find an effect and the numbers don't jump out of the page as ridiculous. A 1% in the measure of randomness has an effect between 1,9% to 3.5%, the  $R^2$  statistics

<sup>&</sup>lt;sup>4</sup>Maurer (1992)

<sup>&</sup>lt;sup>5</sup>The exceptions are Jake Odorizzi, from the Tampa Bay Rays, and Chris Heston, from the San Francisco Giants.

are around 0.1 which makes sense because pitch speed, location and movement taken together are most certainly more important than sequencing.

Further research avenues are plentiful. Probably the most important one is finding a way to take information from the third test and make it actionable. Probably the easiest way is computing the sum per sequence to see which ones repeat more often or, maybe looking for runs of sequences, something along those lines. Also on the third test, it would be interesting to try with longer multi-year sequences and up the block length.

The second test teases the possibility of a more granular analysis. Instead of binary categories, it could be tested, for example, using 8 or 17 pitch zones (4 for strikes and 4 for balls, and 9 and 8, respectively) or testing each pitch type instead of combining them.

An obvious expansion is to implement different randomness tests, either that examine the same randomness properties and check if the results hold, or that check different properties and derive new actionable information.

Another interesting possibility is to consider this as a catcher's game calling problem. Making this analysis is trivially easy with the tools developed but too time consuming to include in this article.
